Full Urine Analysis (FUA)

1 Gross appearance

Physical observation of volume and color

2 Microscopy

Microscopic examination of cells, microorganisms and crystals

3 Biochemistry

Biochemical determinations for pH, osmolarity, protein, urea, creatine, glucose

Test	Results
Urine Urobilinogen	 0.1 1(16) 2(33) 4(66) 8(131) mg/dl (μ mol/L) Normal
Urine Glucose	 neg. ± 100(5.5) +250(14) ++500(28) +++1000(55) mg/dl (mmol/L)

Urine Nitrites	 neg. trace pos.
Urine Leukocytes	 neg. +25 ++75 ++500 WBC/μ L

The Factors Affecting The composition of Urine

- Diet and nutritional status
- Condition of body metabolism
- Kidney function
- Level of contamination with pathogenic microorganisms (bacteria) or even non-pathogenic microflora

1.3 The Composition of Urine

Normal Urine Constituents

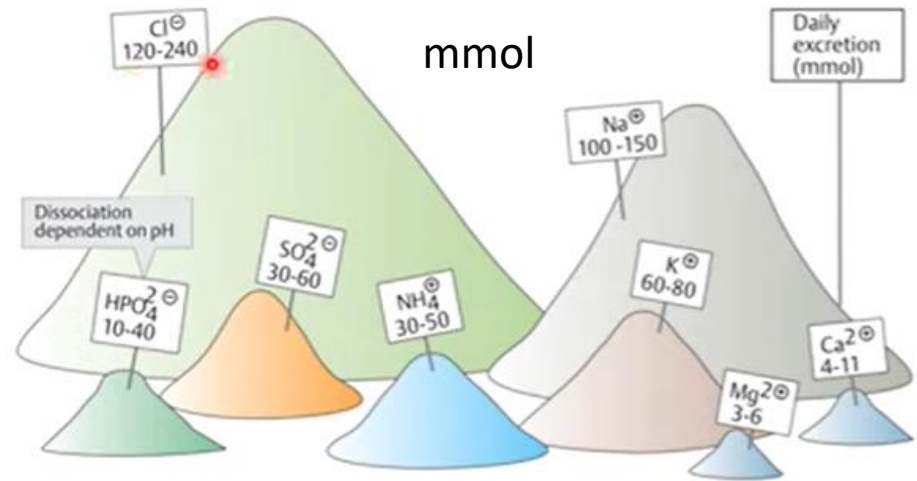

- Water (about 95% of urine)
- Urea
- Creatinine
- Uric acid

Abnormal Urine Constituents

- Glucose
- Protein
- Bile pigments
- Blood cells

TABLE 23.2 Properties and Composition of Urine

Physical Properties		
Specific gravity	1.001–1.028	
Osmolarity	50–1,200 mOsm/L	
pH	6.0 (range 4.5–8.2)	
Solute	Concentration*	Output**
Inorganic Ions		
Chloride	533 mg/dL	6.4 g/day
Sodium	333 mg/dL	4.0 g/day
Potassium	166 mg/dL	2.0 g/day
Phosphate	83 mg/dL	1 g/day
Ammonia	60 mg/dL	0.68 g/day
Calcium	17 mg/dL	0.2 g/day
Magnesium	13 mg/dL	0.16 g/day
Nitrogenous Wastes		
Urea	1.8 g/dL	21 g/day
Creatinine	150 mg/dL	1.8 g/day
Uric acid	40 mg/dL	0.5 g/day
Urobilin	125 µg/dL	1.52 mg/day
Bilirubin	20 µg/dL	0.24 mg/day

Koolman J, Röhm KH, Wirth J, & Robertson M. 2005. Color Atlas of Biochemistry. Vol 2. Stuttgart: Thieme.

COMPOSITION OF URINE

- Normal urine contains about 50 g of solids dissolved in about 1.5 L of water per day.

The chief organic solids are:

- (1) NPN compounds
- (2) Organic acids
- (3) Sugars

The chief inorganic solids are :

- (1) Chloride, (2) Sodium, (3) Potassium, (4) Phosphate, (5) Ammonia

I. NPN COMPOUNDS

- The non-protein nitrogenous (NPN) compounds include:
 - Intermediary (amino acids and creatine)
 - End products (urea, uric acid, and creatinine) of protein metabolism
- The total urinary NPN is on average **25g/** day

A. Urea

- Urea is the chief end product of protein metabolism in human
- It is formed in the liver from the ammonia resulting from the deamination of the amino acids
- It is excreted by the kidneys in the urine
- Its excretion in the urine is more directly affected by protein intake & catabolism than other nitrogenous compounds, which tend to remain relatively constant

Ammonia + CO₂

Carbamoyl phosphate

Ornithine

Citrulline

Argininosuccinate

Arginine

Urea

- Urinary urea is normally 12-25, **average 21 g/day**
- ↑ urinary urea:
 - high protein diet
 - increased protein catabolism (fevers, DM, Cushing syndrome and hyperthyroidism)
- ↓ urinary urea:
 - low protein diet
 - increased protein anabolism (pregnancy and lactation)
 - liver failure (decreased formation)
 - acute renal failure (due to retention)

B. AMINO ACIDS

- 80% of excreted AA in urine are conjugated amino acids:
 - glycine with benzoic acid (found in berries, other fruits)
 - glutamine with phenylacetic acid (found in drugs, BB)
- 20% are free amino acids (escape reabsorption)
- The total urinary amino acid nitrogen normally varies between 0.5-1.0, average 0.7g/day.

Increased urinary amino acids (aminoaciduria)

1. Decreased Deamination of Amino Acids:

- Liver failure:
 - deamination of amino acids and urea formation ↓
 - → generalized aminoaciduria
- Specific aminoacidurias:
 - Caused by defective metabolism of specific amino acids
 - eg., phenylketonuria causes increased excretion of phenylalanine in the urine

2. Inability of the Kidneys to reabsorb Amino Acids:

- In severe nephritis & Fanconi syndrome (PCT problem) the kidneys fail to reabsorb **all** amino acids → generalized aminoaciduria
- Cystinuria: kidneys fail to reabsorb cystine, ornithine, arginine and lysine (**COLA**) leading to their excretion in the urine.

3. Ingestion of certain toxic substances:

- These include:
 - benzoic acid (conjugated with glycine)
 - phenylacetic acid (conjugated with glutamine)
 - Bromobenzene (industrial solvent; conjugated with cysteine)

- excretion of large amounts of these amino acids in the urine

Ammonia (inorganic):

- **Urinary** ammonia is synthesized in the distal convoluted tubules
 - 60% are produced by the action of the enzyme glutaminase on the glutamine received by the kidneys from other tissues
 - 40% are produced by the deamination of other amino acids in the kidneys

Ammonia trapping as glutamine

Glutamate is critical to intracellular AA metabolism

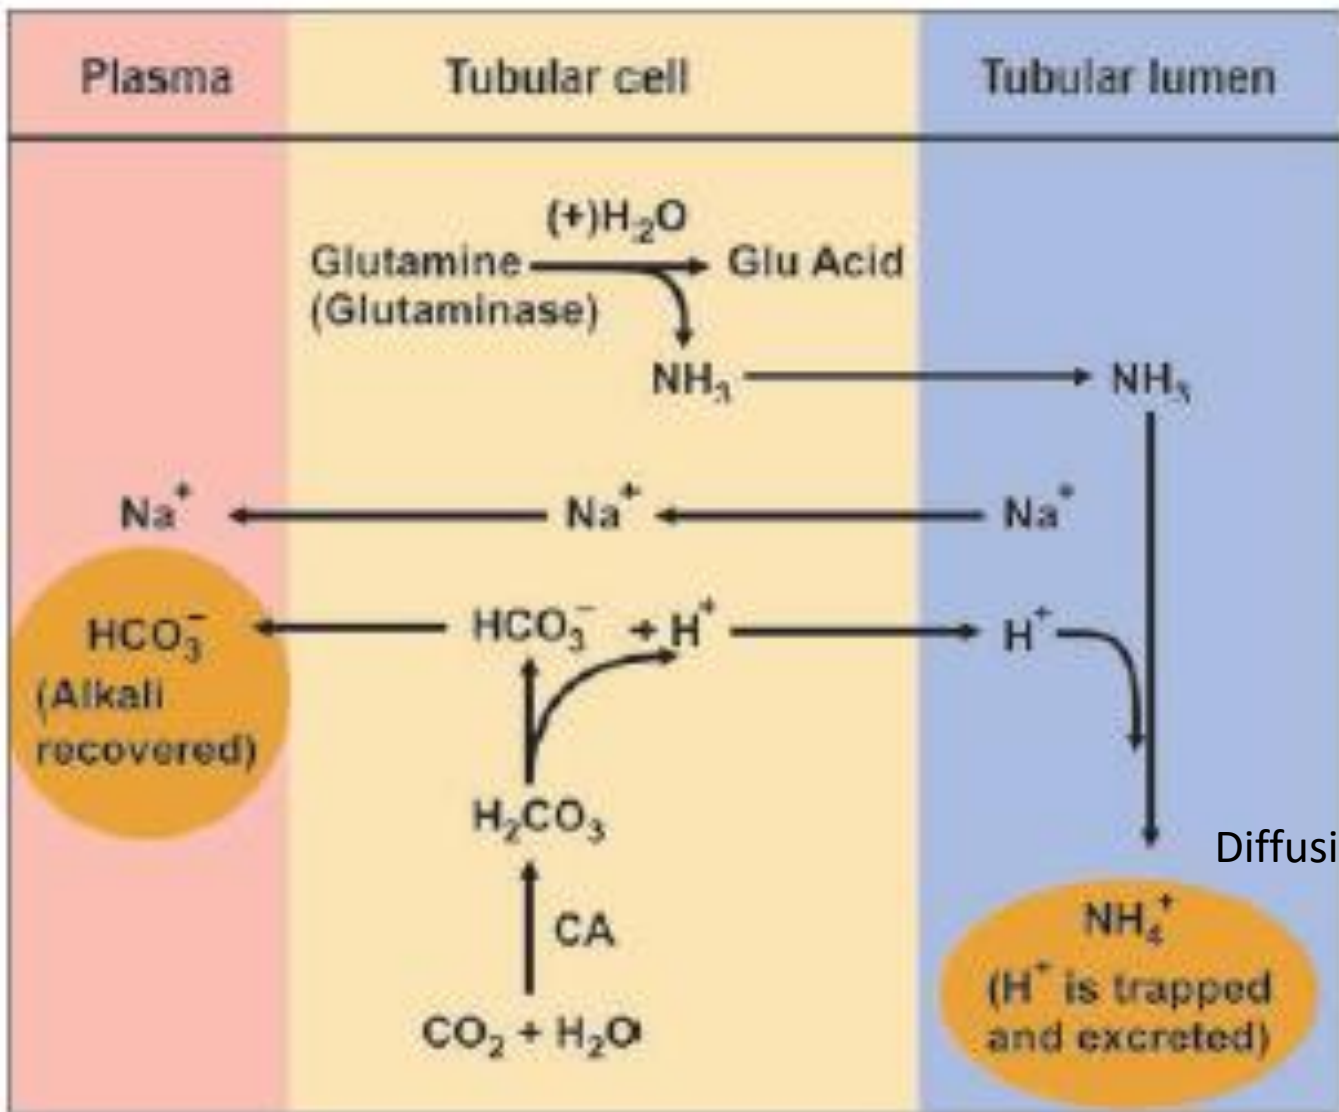

Glutamate synthetase: mitochondrial enzyme, high concentration in brain, liver & kidney

- Urinary ammonia appears to be entirely concerned with the acid-base balance
 - In conditions of acidosis → reabsorption of Na^+ by $\text{Na}^+ : \text{H}^+$ exchange occurs to a limited extent being stopped when the pH of the glomerular filtrate becomes 4.8
 - Ammonia is secreted by the distal convoluted tubules to neutralize this high acidity allowing $\text{Na}^+ : \text{H}^+$ exchange to continue and the alkali reserve to be regained

Diffusion trapping

- Urinary ammonia is normally 0.3 - 1.2, average **0.7 g/day**
- ↑ Urinary ammonia:
 - Acidosis (up to 10 g/day)
 - Hydrolysis of urea by bacteria either in the bladder (cystitis) or if the urine sample is stored without preservative
- ↓ Urinary ammonia:
 - Alkalosis (almost absent)
 - Severe nephritis:
 - ↓ capacity of the kidneys to deaminate amino acids

Response to acidosis

- The enhanced activity of glutaminase and increased excretion of NH_4 takes about 3-4 days to set in under conditions of acidosis
- But once established, it has high capacity to eliminate acid
- Normally, about 70 mEq/L of acid is excreted daily; but in condition of acidosis, this can rise to 400 mEq/day

II. Organic Acids

A. Oxalic acid

- Urinary oxalic acid is mostly exogenous, being derived from foods containing oxalates (spinach, artichokes, tomatoes, strawberries, mangoes, apricots and peaches)
- A small part is endogenous, being derived from the metabolism of glycine or from the metabolism of ascorbic acid
- Very small amounts of oxalates are normally excreted in the urine (10 - 30 mg/day), mostly in the form of calcium oxalate
- ↑ urinary oxalates (hyperoxaluria) may be dietary or the intake of large amounts of vitamin C. It also occurs in an error in glycine metabolism called "primary hyperoxaluria"
- Hyperoxaluria leads to the formation of calcium oxalate stones in the renal tract.

Primary hyperoxaluria:

- Congenital disease caused by decreased metabolism of glyoxylic acid either by:
 - oxidative decarboxylation to formic acid
 - transamination to glycine
- Accumulated glyoxylic acid is oxidized to oxalic acid
- There is excretion of large amounts of oxalate in urine
- Oxalate reacts with calcium forming the insoluble Ca-Oxalate → leads to the formation of Ca-Oxalate stones

Fate of glyoxylic acid

glyoxylic acid

Glycine

glyoxylic acid

glyoxylic acid

urine

B. Lactic acid

- Lactic acid is the end product of glycolysis in erythrocytes and in muscles during exercise
- It mostly goes to the liver where it becomes converted to glucose
- Little lactic acid is excreted in the urine (50 -200 mg / day)

C. Citric acid

- The citric acid in urine is mostly derived from intermediary metabolism
- Some citric acid is excreted in the urine 200-1200 mg/day

Cori Cycle

D. Ketone bodies:

- The ketone bodies include: acetone, acetoacetic acid, and β -hydroxybutyric acid
- They are formed in the liver as intermediates in the metabolism of fatty acids
- Small amounts of ketone bodies (less than 15 mg/day on an average diet, and up to 100 mg/day on a high fat diet), mostly β -hydroxybutyric acid, are excreted in the urine
- Their excretion markedly increases in ketosis

Ketone Bodies Pathogenesis

Glucose (Provide energy)

Insufficient intake
1. Starvation

Uncontrolled
Diabetes Mellitus

Low-Insulin

Breakdown of fats

Lipolysis + Reesterification

Liver
↓ Tissue metabolism + ↑ Ketone bodies

Free fatty acids

Plasma fatty acids

Oxidation

Acetoacetate 20%
↓
Acetone 2%
↓
 β Hydroxybutyrate 78%

Decarboxylation

Blood

Diabetic Ketoacidosis

E. Hippuric Acid

- Hippuric acid is the product of detoxication of **benzoic acid**, by conjugation with **glycine**
- Benzoic acid is present in many fruits and vegetables, especially in plums and prunes
- It is used as preservative in some food products, such as jams and ketchup
- It also results from the action of intestinal bacteria on phenylalanine
- The amount of hippuric acid excreted in the urine is related to the dietary intake of benzoic acid as well as to intestinal putrefaction
- It normally ranges between 0.1 and 1.0 g/day

III. Sugars

- Normally not more than 1 g of sugars is excreted in the urine per day
- The chief sugar is glucuronic acid (about 0.5 g/day). which is present in urine conjugated with xenobiotics
- In addition, smaller quantities of glucose , lactose, and L-arabinose may be present in urine.

Xenobiotics are foreign organic substances, which are substances not normally metabolized in the body. Xenobiotics of medical importance include drugs, toxins, food additives.

IV. Proteins

- Urine of normal subjects contains small amounts of glycoproteins, which are derived from the mucous glands of the renal tract. Tracts of albumin (< 30 mg /day) are excreted in urine. They cannot be detected by the heat coagulation test.

ABNORMAL CONSTITUENTS

I. Proteinuria :

- This is the presence of detectable amounts of proteins in the urine. It may be:

A- Prerenal Proteinuria

1. **Albuminuria:** This occurs in heart failure due to increased renal venous pressure
2. **Bence Jones Proteinuria:** this is an abnormal globulin, composed of light chains only (22–24 kDa), formed by malignant plasma cells (multiple myeloma)

3. **Myoglobinuria:** Myoglobinuria occurs in crush syndrome and in myocardial infarction due to release of myoglobin from crushed skeletal muscles and heart, respectively

4. **Hemoglobinuria:** Hemoglobin appears in the blood plasma and in the urine if intravascular hemolysis occurs, e.g., in hemolytic anemia and in malaria

Collapsed building from 1985 Mexico earthquake.
Earthquakes are a main cause of crush syndrome

B-Renal Proteinuria

- This is due to kidney affection
 - Albumin, having a **higher plasma concentration** and a **lower molecular weight**, appears in the urine in higher concentrations than globulins, and hence the name albuminuria.
1. False Albuminuria (Functional Albuminuria):
 - This is not pathological; no organic lesion is detectable in the kidneys. It is intermittent, occurring only when the renal venous pressure increases, e.g., during muscular exercise and on assumption of the erect posture (orthostatic), and disappears on lying down. Thus, it is absent in the morning sample, and only present in the day samples.

2. Microalbuminuria:

- Albumin is detected by ordinary tests only if urinary albumin exceeds 200 mg/d
- Levels between 20 and 200 mg/L, called microalbuminuria, can only be detected by special tests
- It is an early sign of glomerular affection in uncontrolled diabetes mellitus

3. True Albuminuria :

- This is pathological
- It is more commonly due to lesions of the renal glomeruli (e.g. glomerulonephritis)

B-Postrenal Proteinuria

- This is caused by inflammation, tumors, or stones of the renal tract, leading to the secretion of mucus and the passage of blood (albumin, globulins, and hemoglobin) in the urine.

II. Glycosuria:

- This term has long been used to indicate the presence of detectable amounts of glucose in the urine
- More properly, it should be used to indicate the presence of any sugar in the urine, these include glucose, fructose, galactose, pentoses, or lactose.

III. Chyluria

- Chyluria is the presence of absorbed fat (chylomicrons) in the urine
- It rarely follows the ingestion of large amounts of fats, particularly in severe diabetic patients (decreased clearance of chylomicrons and VLDL due to decreased activity of lipoprotein lipase)
- It may also be caused by an abnormal connection between the intestinal lymphatics and the urinary tract
- This may be congenital and may be caused by filariasis
- The urine acquires a milky appearance that disappears upon shaking with ether

IV. Choluria

- Choluria is the appearance of bile in the urine. It includes:
 1. Bilirubin and Bile Salts: Bilirubin and bile salts appear in the urine in obstructive Jaundice
 - due to obstruction of the biliary passages and regurgitation of bile into the blood
 2. Urobilinogen: Urobilinogen is normally present in the urine in very small amounts (less than 4 mg/day)
 - It markedly increases hemolytic jaundice

V. Ketonuria

- Ketonuria is the presence of delectable amounts of ketone bodies in the urine.
